

OPTIMAL DESIGNS FOR TWO-LEVEL FACTORIAL EXPERIMENTS WITH BINARY RESPONSE

Abhyuday Mandal¹, Jie Yang² and Dibyen Majumdar²

¹*University of Georgia* and ²*University of Illinois*

Abstract:

We consider the problem of obtaining locally D-optimal designs for factorial experiments with qualitative factors at two levels each with binary response. Our focus is primarily on the 2^2 experiment. In this paper, we derive analytic results for some special cases and indicate how to handle the general case. The performance of the uniform design is examined and we show that this design is highly efficient in general. For the general 2^k case we show that the uniform design has a *maximin* property.

Key words and phrases: Generalized linear model, full factorial design, D-optimality, information matrix, uniform design, cylindrical algebraic decomposition.

1. Introduction

The goal of many scientific and industrial experiments is to study a process that depends on several qualitative factors. We will focus on the design of those experiments where the response is binary. If the response was quantitative and a linear model was appropriate, then the design of the experiment is informed by the extensive literature on factorial experiments. On the other hand if the factors were quantitative and the response was binary, the literature on optimal design of generalized linear models in the approximate theory setup could be used. The goal of our work is to initiate the optimal design theory for factorial experiments with binary response.

Specific examples of experiments of the type we are interested in are available in different areas of application. Smith (1932) describes a bioassay for an anti-pneumococcus serum where the explanatory variable is doses of the serum. Mice infected with pneumococcus are injected with different doses of the serum and

the response is survival (or not) beyond seven days. Hamada and Nelder (1997) discussed the advantages of using a generalized linear model for discrete responses instead of linearizing the response to obtain an approximate linear model. They examined an industrial experiment on windshield molding performed at an IIT Thompson plant that was originally reported by Martin, Parker and Zenick (1987). There were four factors each at two levels and the response was whether the part was *good* or not. A 2^{4-1} fractional factorial design was used with 1000 runs at each experimental condition. Other examples include a seed germination experiment described in Crowder (1978), a sperm survival experiment in Myers, Montgomery and Vining (2002) and a designed experiment on the reproduction of plum trees reported by Hoblyn and Palmer (1934).

We assume that the process under study may be adequately described by a generalized linear model. While the theory we develop will work for any link function, in examples and simulations we focus on the logit, probit, log-log, and complementary log-log links. The optimal designs will be obtained using the D-criterion that maximizes the determinant of the inverse of the asymptotic covariance matrix of the estimators (the information matrix). In order to overcome the difficulty posed by the dependence of the design optimality criterion on the unknown parameters, we use the local optimality approach of Chernoff (1953) where the parameters are replaced by assumed values. We refer the reader to the paper by Khuri, Mukherjee, Sinha and Ghosh (2006) for details of theory of designs for generalized linear models.

We will assume that every factor is at two levels, a setup of particular interest in screening experiments, and that (for an experiment with k factors) we are interested in a *complete* 2^k experiment, i.e., the design may be supported on all 2^k points. The model we choose may include a subset of all main effects and interactions. If we assume that the total number of observations is held fixed, then the design problem is to determine the proportion of observations allocated to each of the 2^k design points. It may be noted that if the response follows a standard linear model, then it follows from the results of Kiefer (1975) that the design which is *uniform* on the 2^k design points is universally optimal. For the problem restated in terms of weighing design, Rao (1971) gave the optimality

of the uniform design in terms of minimizing variances of each of the parameter estimators. It may be noted that the uniform design is an *orthogonal array* (Rao (1947)).

In this initial study, we focus primarily on the complete 2^2 experiment where the response is binary. While we do not find analytic solutions for D-optimal design for the general 2^2 experiment, we obtain characterizations for several special cases. For the general 2^2 experiment we indicate how a solution may be obtained by *Cylindrical Algebraic Decomposition* (CAD). We also examine uniform designs and show that these are highly efficient in general.

For the general 2^k experiment we show that the uniform design is maximin D-optimal design, i.e., a design that maximizes a lower bound of the D-criterion.

In section 2 we give the preliminary setup. Results for the 2^2 experiment are proved in section 3. In section 4 we study robustness of the uniform design, and in section 5 we consider the general 2^k experiment. Some concluding remarks are given in section 6. Proofs are relegated to the appendix and details are also available under the supplementary materials.

2. Preliminary Setup

Consider a 2^k experiment, i.e., an experiment with k explanatory variables at 2 levels each. Suppose n_i units are allocated to the i th experimental condition such that $n_i \geq 0$, $i = 1, \dots, 2^k$, and $n_1 + \dots + n_{2^k} = n$. We suppose that n is fixed and consider the problem of determining the “optimal” n_i ’s. In fact, we write our optimality criterion in terms of the proportions:

$$p_i = n_i/n, \quad i = 1, \dots, 2^k$$

and determine the “optimal” p_i ’s. (Since n_i ’s are integers, an optimal design obtained in this fashion may not be “feasible” - an issue we will not deal with, except to say that a feasible solution “near” an optimal solution is expected to be “nearly optimal”).

Suppose η is the linear predictor that involves main effects and interactions which are assumed to be in the model. Our main focus in this initial research on

the topic will be the 2^2 experiment with main-effect model, in which case $\eta = \beta_0 + \beta_1 x_1 + \beta_2 x_2$ and $\beta = (\beta_0, \beta_1, \beta_2)'$. In the framework of generalized linear models, the response Y is linked to the linear predictor by the link function g : $E(y) = \mu$, $\eta = g(\mu)$ (McCullagh and Nelder (1989)). For a binary response, the commonly used link functions are logit, probit, log-log, and complimentary log-log links.

The maximum likelihood estimator of β has an asymptotic covariance matrix (Khuri, Mukherjee, Sinha and Ghosh (2006)) that is the inverse of $nX'WX$, where $W = \text{diag}(w_1 p_1, \dots, w_{2^k} p_{2^k})$, $w_i = \left(\frac{d\mu_i}{d\eta_i}\right)^2 / (\mu_i(1 - \mu_i)) \geq 0$ and X is the “design matrix”. For a main-effect 2^2 experiment, for instance, $X = ((1, 1, 1, 1)', (1, 1, -1, -1)', (1, -1, 1, -1)')$. The matrix $X'WX$ may be viewed as the *per-observation* information matrix. The *D-optimality* criterion maximizes the determinant $|X'WX|$.

3. D-Optimal 2^2 Designs

If $k = 2$, for a main-effect plan, the asymptotic information matrix is proportional to $X'WX$. It can be shown that $|X'WX|$ can be written as (except for the constant 16):

$$\begin{aligned} \det(\mathbf{w}, \mathbf{p}) = G(\mathbf{p}) &= p_2 w_2 \cdot p_3 w_3 \cdot p_4 w_4 + p_1 w_1 \cdot p_3 w_3 \cdot p_4 w_4 \\ &+ p_1 w_1 \cdot p_2 w_2 \cdot p_4 w_4 + p_1 w_1 \cdot p_2 w_2 \cdot p_3 w_3 \end{aligned} \quad (3.1)$$

where $\mathbf{w} = (w_1, w_2, w_3, w_4)'$ and $\mathbf{p} = (p_1, p_2, p_3, p_4)'$. In this section, we will consider the problem of maximizing $G(\mathbf{p})$ over all vectors $\mathbf{p}$ with $p_i \geq 0$ and $\sum_i p_i = 1$.

3.1 Analytic solutions to special cases

It follows from Kiefer (1975) that if all the w_i 's are equal then the uniform design ($p_1 = p_2 = p_3 = p_4 = 1/4$) is D-optimal. If one and only one of the w_i 's is zero, then the optimal design is uniform over the design points that correspond to the nonzero w_i 's, and if two or more w_i 's are zero, then $G(\mathbf{p}) \equiv 0$. From now on, we assume $w_i > 0$, $i = 1, 2, 3, 4$. Define $L = G/(w_1 w_2 w_3 w_4)$ and $v_i = 1/w_i$, $i = 1, 2, 3, 4$. The maximization problem (3.1) can be rewritten as

maximizing

$$L(\mathbf{p}) = v_4 p_1 p_2 p_3 + v_3 p_1 p_2 p_4 + v_2 p_1 p_3 p_4 + v_1 p_2 p_3 p_4. \quad (3.2)$$

Although the objective function (3.2) is elegant, an analytic solution with general $v_i > 0$ is not available. In this subsection, analytic solutions are obtained for some special cases.

Theorem 3.1.1 *$L(\mathbf{p})$ has a unique maximum at $\mathbf{p} = (0, 1/3, 1/3, 1/3)$ if and only if $v_1 \geq v_2 + v_3 + v_4$.*

Note that this does not correspond to a complete 2^2 experiment, rather it corresponds to a design supported only on three points, which is saturated for the main effects plan $\eta = \beta_0 + \beta_1 x_1 + \beta_2 x_2$. For the logit link function, $0 \leq w_i \leq 0.25$. Computations under the simulation condition that w_i iid $\sim$ uniform(0,0.25) show that the chance of obtaining a saturated solution is 48%. For other link functions, the chances are similar.

Lemma 3.1.1 *If $v_1 > v_2$, then any solution to the maximization problem of (3.2) must satisfy $p_1 \leq p_2$; if $v_1 = v_2$, then any solution must satisfy $p_1 = p_2$.*

Theorem 3.1.2 *Suppose $v_1 \geq v_2$, $v_3 = v_4 = v$, and $v_1 < v_2 + 2v$. Then the solution maximizing (3.2) is*

$$p_1 = \frac{1}{2} - \frac{v_1 - v_2 + 4v}{2(-2\delta + D)}, p_2 = \frac{1}{2} + \frac{v_1 - v_2 - 4v}{2(-2\delta + D)}, p_3 = p_4 = \frac{2v}{-2\delta + D} \quad (3.3)$$

with $L = 2v^2 (\delta^2 + 4v_1 v_2 - \delta D) / (-2\delta + D)^3$, where $\delta = v_1 + v_2 - 4v$ and $D = \sqrt{\delta^2 + 12v_1 v_2}$.

Corollary 3.1.1 *Suppose $v_2 = v_3 = v_4 = v$ and $v_1 < 3v$. Then the solution maximizing (3.2) is*

$$p_1 = \frac{3v - v_1}{9v - v_1}, p_2 = p_3 = p_4 = \frac{2v}{9v - v_1}$$

with the maximum $L = 4v^3 / (9v - v_1)^2$.

Corollary 3.1.2 *Suppose $v_1 = v_2 = u$, $v_3 = v_4 = v$, and $u > v$. Then the*

solution maximizing (3.2) is

$$p_1 = p_2 = \frac{2u - v - d}{6(u - v)}, \quad p_3 = p_4 = \frac{u - 2v + d}{6(u - v)}$$

with the maximum $L = (2u - v - d)(u - 2v + d)(u + v + d) / [108(u - v)^2]$, where $d = \sqrt{u^2 - uv + v^2}$.

Theorem 3.1.1 reveals that the D-optimal design is saturated if and only if $2\max_i v_i \geq v_1 + v_2 + v_3 + v_4$. We call it the *saturation condition*. In terms of w 's, it is

$$2/\min\{w_1, w_2, w_3, w_4\} \geq 1/w_1 + 1/w_2 + 1/w_3 + 1/w_4. \quad (3.4)$$

Theorem 3.1.3 examines this condition in terms of the β 's.

Theorem 3.1.3 *For the logit link, the saturation condition is true if and only if*

$$\beta_0 \neq 0, \quad |\beta_1| > \frac{1}{2} \log \left(\frac{e^{2|\beta_0|} + 1}{e^{2|\beta_0|} - 1} \right), \quad \text{and}$$

$$|\beta_2| \geq \log \left(\frac{2e^{|\beta_0|+|\beta_1|} + \sqrt{(e^{4|\beta_0|} - 1)(e^{4|\beta_1|} - 1)}}{(e^{2|\beta_0|} - 1)(e^{2|\beta_1|} - 1) - 2} \right).$$

Figure 1: Lower boundary of the region satisfying the saturation condition

Figure 1 shows how the region satisfying the saturation condition changes with β_0 . For fixed β_0 , a pair (β_1, β_2) satisfies the saturation condition if and only if the corresponding point in Figure 1 is above the curve labelled by β_0 .

For logit link, $\beta_0, \beta_1, \beta_2$ are symmetric with respect to w_1, w_2, w_3, w_4 . If we permute $\beta_0, \beta_1, \beta_2$, we only need to change the order of w_1, w_2, w_3 accordingly. It won't affect whether or not the saturation condition is satisfied. Therefore, we can get parallel results to Theorem 3.1.3 in any order of $\beta_0, \beta_1, \beta_2$.

3.2 Exact solution using computer-aid optimization

For given values of v_1, v_2, v_3, v_4 , depending on the computational resources, one can always try to apply some numerical searching algorithm such as Nelder-Mead, quasi-Newton, conjugate-gradient, or simply a grid search. However, such solutions will not be very accurate in general.

For general cases other than the special ones discussed above, one may use *cylindrical algebraic decomposition* (CAD) (Fotiou et al. (2005)) to find an exact solution maximizing (3.2). For given v_1, v_2, v_3, v_4 , the CAD algorithm partitions the feasible domain of (L, p_1, p_2, p_3) into a finite union of disjoint homogeneous cells in terms of polynomial constraints. The cell with greatest L provides us a solution. However, it is difficult, if not computationally infeasible, to get explicit formula involving general v_1, v_2, v_3, v_4 .

Besides the CAD approach, one may also use the Lagrange multipliers or the Karush-Kuhn-Tucker (KKT) conditions (Karush (1939), Kuhn and Tucker (1951)) to find all the local extrema of L , and then pick the largest one. For general v_1, v_2, v_3, v_4 , this approach leads to two polynomial equations of order 4 each. No explicit formula involving general v_1, v_2, v_3, v_4 is available.

3.3 Analytic approximate solution

For the optimization problem (3.2), we do not find analytic solutions for the general case. In this section, we will propose an analytic approximate solution. To simplify notations, write $L[v_1, v_2, v_3, v_4]$ for $\max_{\mathbf{p}} L$, given v_1, v_2, v_3, v_4 . For

example, Theorem 3.1.2 corresponds to $L[v_1, v_2, v, v]$. Without any loss of generality, we assume $v_1 < v_2 < v_3 < v_4$ and $v_4 < v_1 + v_2 + v_3$. Define

$$L_{34} = L[v_1, v_2, (v_3 + v_4)/2, (v_3 + v_4)/2]$$

and $L_{12}, L_{13}, L_{14}, L_{23}, L_{24}$ accordingly. The strategy is to use $\max\{L_{12}, L_{23}, L_{34}\}$ to approximate $\max_{\mathbf{p}} L$ based on the theorem as follows.

Theorem 3.3.4 *Assume $v_1 < v_2 < v_3 < v_4$ and $v_4 < v_1 + v_2 + v_3$. Then*

$$\begin{aligned} \max\{L_{13}, L_{14}, L_{24}\} &\leq \max\{L_{12}, L_{23}, L_{34}\}, \\ \max_{\mathbf{p}} L - \max\{L_{12}, L_{23}, L_{34}\} &\leq \min\left\{\frac{v_2 - v_1}{216}, \frac{v_3 - v_2}{96\sqrt{3}}, \frac{v_4 - v_3}{54}\right\}. \end{aligned}$$

We call the best $\mathbf{p}$ among the solutions to L_{12}, L_{23} , or L_{34} the *analytic approximate solution*, and denote it by $\mathbf{p}_a$. Then $L(\mathbf{p}_a) = \max\{L_{12}, L_{23}, L_{34}\}$. Theorem 3.3.4 provides a theoretical upper bound for the difference $\max_{\mathbf{p}} L - L(\mathbf{p}_a)$.

To see how our approximation works numerically, we randomly selected 1000 $\mathbf{w} = (w_1, w_2, w_3, w_4)$ with $0.05 \leq w_i \leq 0.25$. For each randomly chosen $\mathbf{w}$, we calculate the optimal $\mathbf{p}$ using CAD and denote it by $\mathbf{p}_o$. We also calculate the analytic solution based on Theorems 3.1.1, 3.1.2, or 3.3.4 and denote it by $\mathbf{p}_*$. If the saturation condition (3.4) is satisfied or $w_i = w_j$ for some $i \neq j$, then $\mathbf{p}_* = \mathbf{p}_o$. Otherwise, the analytic approximate solution based on Theorem 3.3.4 is applied, and $\mathbf{p}_* = \mathbf{p}_a$. Then we calculate the determinant of the information matrix and denote it by D_o and D_* for $\mathbf{p}_o$ and $\mathbf{p}_*$, respectively. In Figure 2, we plot the relative loss $(D_o^{1/3} - D_*^{1/3}) / D_o^{1/3}$ versus $D_o^{1/3}$. Numerical results show that 96% of the relative losses are less than 0.03% and the maximum relative loss is about 0.085%. So the analytic approximation solution works very well.

Since v_i 's depend on the assumed values, they are in general not quantified accurately at the planning stage. The results in this section show that setting some v_i 's to be equal is not a bad strategy. The analytic approximation is also potentially useful for future theoretical research in this area.

Figure 2: Efficiency of the approximate solutions

4. Robustness of uniform design

If the experimenter is unable to make an informed choice of the assumed values for local optimality, the natural design choice is the uniform design $\mathbf{p}_u = (1/4, 1/4, 1/4, 1/4)$. The relative loss of efficiency of $\mathbf{p}_u$ with respect to the true $\mathbf{w} = (w_1, w_2, w_3, w_4)$ is:

$$R_u(\mathbf{w}) = \frac{\det(\mathbf{w}, \mathbf{p}_t)^{1/3} - \det(\mathbf{w}, \mathbf{p}_u)^{1/3}}{\det(\mathbf{w}, \mathbf{p}_t)^{1/3}} = 1 - \frac{1}{4} \left(\frac{v_1 + v_2 + v_3 + v_4}{L(\mathbf{p}_t)} \right)^{1/3},$$

where $v_i = 1/w_i$, $\mathbf{p}_t$ is the optimal design under $\mathbf{w}$, and $L(\mathbf{p}_t)$ is defined in (3.2). To study the maximum loss of efficiency, we consider $R_{\max}^{(u)} = \max_{\mathbf{w}} R_u(\mathbf{w})$. The following theorem finds the values of $R_{\max}^{(u)}$ for different values of $\mathbf{w}$'s.

Theorem 4.1.5 *Without any loss of generality, assume $v_1 \geq v_2 \geq v_3 \geq v_4$. Then*

$$R_{\max}^{(u)} = \begin{cases} 1 - \frac{3}{4} \left(1 + \frac{3a}{b} \right)^{1/3} & \text{if } v_1 \geq v_2 + v_3 + v_4 \text{ with } 0 < a \leq v_i \leq b \\ 1 - \frac{3}{4} \times 2^{1/3} & \text{if } v_1 < v_2 + v_3 + v_4 \end{cases}$$

If $v_1 < v_2 + v_3 + v_4$, the maximum loss of the uniform design is $1 - \frac{3}{4} \times 2^{1/3} \approx 0.055$ regardless of the choice of link functions. The uniform design clearly performs

very well. Now, let us consider the saturation condition $v_1 \geq v_2 + v_3 + v_4$. For some reasonable choices of $\mathbf{w}$'s, Table 4.1 gives results for popular link functions. These $R_{\max}^{(u)}$'s are significantly larger than 0.055. Moreover, the efficiency of the uniform design gets worse as a decreases to zero. This is intuitive because as a decreases, $2v_{\max} - \sum v_i$ increases, worsening the performance of uniform design. Nevertheless, based on Theorem 3.1.1, if we *know* that $v_1 \geq v_2 + v_3 + v_4$ the design of choice clearly is the saturated design $(0, 1/3, 1/3, 1/3)$. We will discuss the utility of saturated designs in practical applications in section 6. It can be seen from Theorem 4.1.5 that in general the maximum loss of efficiency is $1/4$.

Table 4.1: *Maximum* loss of efficiency for $v_1 \geq v_2 + v_3 + v_4$

	Link functions	
	Logit	Probit or (complementary) log-log
	$0.05 \leq w \leq 0.25$	$0.05 \leq w \leq 0.65$
$R_{\max}^{(u)}$	0.123	0.196

5. General case: 2^k experiment

The general case of 2^k factorial is technically complicated. We have some results for particular cases that will be reported in future publications. In this section we will show that the uniform design $(p_1 = \cdots = p_{2^k} = \frac{1}{2^k})$ has a *maximin* optimality property, i.e., it maximizes a lower bound of the *D-criterion*.

Suppose there are q parameters (main effects and interactions) in the chosen model for the 2^k experiment, i.e. β is a $q \times 1$ vector and the design matrix X is $2^k \times q$. The matrix X can be extended to the $2^k \times 2^k$ design matrix F of the “full model”, i.e., one that includes all main effects and interactions. Note that F is a Hadamard matrix, i.e., $F'F = 2^k I_{2^k}$, where I_{2^k} is the identity matrix of order 2^k . Moreover, we can partition F as $F = (X|R)$ where R contains all effects that are not in the chosen model. Clearly,

$$|F'WF| = |X'WX| \left| R'WR - R'WX (X'WX)^{-1} X'WR \right| \leq |X'WX| |R'WR|.$$

Hence

$$|X'WX| \geq \frac{|F'WF|}{|R'WR|}.$$

Note that $|F'WF| = 2^{kq} \Pi w_i \Pi p_i$, and $|R'WR| \leq (w_M)^{2^k - q} |R'PR|$ where $w_M = \max\{w_1, \dots, w_{2^k}\}$, and $P = \text{diag}(p_1, \dots, p_{2^k})$. It follows from Proposition 1' of Kiefer (1975) that the uniform design $p_1 = \dots = p_{2^k} = \frac{1}{2^k}$ maximizes $|R'PR|$. Hence we obtain a *lower bound* to the *D-criterion*

$$|X'WX| \geq \frac{2^{k2^k} \Pi w_i \Pi p_i}{(w_M)^{2^k - q}}.$$

This lower bound is a maximum when $p_1 = \dots = p_{2^k} = \frac{1}{2^k}$, which gives a maximin property of the uniform design.

How good is the uniform design? The loss of efficiency corresponding to the uniform design is

$$R_u(w) = 1 - \left(\frac{|X' \text{diag}(w_1/2^k, \dots, w_{2^k}/2^k) X|}{\max |X'WX|} \right)^{1/q}.$$

Then it can be shown that

$$R_u(w) \leq 1 - \frac{|X'W_0X|^{1/q}}{2^k w_M} \leq 1 - \frac{w_m}{w_M}$$

where $w_m = \min\{w_1, \dots, w_{2^k}\}$ and $W_0 = \text{diag}(w_1, \dots, w_{2^k})$.

For example, suppose it is known that $0.14 \leq w_i \leq 0.20$. Then the uniform design is not less than 70% efficient, irrespective of the value of k or the X matrix (the model). While this bound enables us to make general statements like this, the results in Theorem 4.1.5 for the 2^2 case shows that this bound can be quite conservative.

6. Discussion

Locally optimal designs require assumed values of the parameters w which may not be readily available at the planning stage. The expression of w_i given in section 2 depends on the assumed values of the parameter β and the link function η . In situations where there is overdispersion, this expression (the nominal

variance) may not be adequate to describe variation in the model, and a more realistic representation for w may be

$$w_i = c_i \left(\frac{d\mu_i}{d\eta_i} \right)^2 / (\mu_i(1 - \mu_i))$$

where c_i is a function of the factor levels $x_1, x_2, \dots, x_k$. This will make the specification of w_i even more difficult. For the design problem, however, it can be seen that we need only the relative magnitudes $w_i^* = w_i/w_M$, which may be easier to specify in some applications. Note that w_i^* take values in the interval $(0, 1]$.

The overall conclusion for the 2^2 factorial experiment with main effects model is that, for the link functions we studied, the locally optimal designs are robust in the sense that the loss of efficiency due to misspecification of the assumed values is not large. If the (assumed) variance at one point is substantially larger than the others, then the D-optimal design is based on only 3 of the 4 points. In real world experiments, however, an experimenter would rarely feel confident to not allocate observations at a point based solely on assumed values, and this is not our recommendation for practice. However, the D-optimal design would still provide a useful benchmark for the efficiency of designs, and to the extent feasible it is wise to dedicate more resources to points that we believe have small variance and less resources to points with large variance. If there is no basis to make an informed choice of the assumed values, we *can* recommend the use of the uniform design.

We have extensive results on the robustness of the 2^2 designs against the misspecification of w , which will be reported in another publication. This paper consists of initial results in this area of optimal designs for two level factorial experiments with binary response. Our research is ongoing on extending these results to more general factorial and fractional factorial experiments.

Appendix

1. Proof of Theorem 3.1.1

(1) If $v_1 \geq v_2 + v_3 + v_4$, then

$$\begin{aligned}
 L &= v_4(p_1p_2p_3 + p_2p_3p_4) + v_3(p_1p_2p_4 + p_2p_3p_4) + v_2(p_1p_3p_4 + p_2p_3p_4) \\
 &\quad + (v_1 - v_2 - v_3 - v_4)p_2p_3p_4 \\
 &= v_4(p_1 + p_4)p_2p_3 + v_3(p_1 + p_3)p_2p_4 + v_2(p_1 + p_2)p_3p_4 \\
 &\quad + (v_1 - v_2 - v_3 - v_4)p_2p_3p_4 \\
 &\leq v_4 \left(\frac{(p_1 + p_4) + p_2 + p_3}{3} \right)^3 + v_3 \left(\frac{(p_1 + p_3) + p_2 + p_4}{3} \right)^3 \\
 &\quad + v_2 \left(\frac{(p_1 + p_2) + p_3 + p_4}{3} \right)^3 + (v_1 - v_2 - v_3 - v_4)p_2p_3p_4 \tag{A.1}
 \end{aligned}$$

$$\begin{aligned}
 &= \frac{v_4}{27} + \frac{v_3}{27} + \frac{v_2}{27} + (v_1 - v_2 - v_3 - v_4)p_2p_3p_4 \\
 &\leq \frac{v_2 + v_3 + v_4}{27} + (v_1 - v_2 - v_3 - v_4) \left(\frac{p_2 + p_3 + p_4}{3} \right)^3 \tag{A.2}
 \end{aligned}$$

$$\begin{aligned}
 &\leq \frac{v_2 + v_3 + v_4}{27} + (v_1 - v_2 - v_3 - v_4) \left(\frac{p_1 + p_2 + p_3 + p_4}{3} \right)^3 \tag{A.3} \\
 &= \frac{v_1}{27}
 \end{aligned}$$

By the inequality of arithmetic and geometric means, the “=” in (A.1) is true if and only if

$$p_1 + p_4 = p_2 = p_3, \quad p_1 + p_3 = p_2 = p_4, \quad \text{and} \quad p_1 + p_2 = p_3 = p_4$$

which implies $p_1 = 0, p_2 = p_3 = p_4 = 1/3$. Note that the “=” in (A.2) is true if $p_2 = p_3 = p_4$, and the “=” in (A.3) is true if $p_1 = 0$. After all, $L = v_1/27$ if and only if $p_1 = 0, p_2 = p_3 = p_4 = 1/3$.

(2) If $\mathbf{p} = (0, 1/3, 1/3, 1/3)$ maximizes (3.2), we claim that $v_1 \geq v_2 + v_3 + v_4$. Otherwise, if $v_1 < v_2 + v_3 + v_4$, the solution $\mathbf{p}_\epsilon = (\epsilon, (1 - \epsilon)/3, (1 - \epsilon)/3, (1 - \epsilon)/3)$ will be better than $\mathbf{p}$ for small enough $\epsilon > 0$. It can be shown that

$$L(\mathbf{p}_\epsilon) > L(\mathbf{p}) \quad \text{if and only if} \quad 3d_1 > \epsilon(3 + 6d_1 - 2\epsilon - 3d_1\epsilon)$$

where $d_1 = (v_2 + v_3 + v_4 - v_1)/v_1 > 0$. □

2. Proof of Theorem 4.1.5

To maximize $R_u(\mathbf{w})$ is equivalent to minimize

$$Q(v_1, v_2, v_3, v_4) = \frac{v_1 + v_2 + v_3 + v_4}{v_1 p_2 p_3 p_4 + v_2 p_1 p_3 p_4 + v_3 p_1 p_2 p_4 + v_4 p_1 p_2 p_3}.$$

where (p_1, p_2, p_3, p_4) is the optimal allocation for the given (v_1, v_2, v_3, v_4) . Note that $v_1 \geq v_2 \geq v_3 \geq v_4$ implies that $p_1 \leq p_2 \leq p_3 \leq p_4$.

(1) If $v_1 \geq v_2 + v_3 + v_4$, then $p_1 = 0$ and $p_2 = p_3 = p_4 = 1/3$ which gives

$$R_u(\mathbf{w}) = 1 - \frac{3}{4} \left(1 + \frac{v_2 + v_3 + v_4}{v_1} \right)^{1/3}.$$

Suppose $0 < a \leq v_i \leq b$ for $i = 1, \dots, 4$, then $v_1 \geq v_2 + v_3 + v_4$ implies $b \geq 3a$ and

$$Q(v_1, v_2, v_3, v_4) = 27 \left[1 + \frac{v_2 + v_3 + v_4}{v_1} \right] \geq 27 \left[1 + \frac{3a}{b} \right].$$

The minimum of Q is attained at $v_1 = b$ and $v_2 = v_3 = v_4 = a$. So $R_{\max}^{(u)} = 1 - \frac{3}{4}(1 + 3a/b)^{1/3}$.

Specifically, if $v_1 = v_2 + v_3 + v_4$, $Q(v_1, v_2, v_3, v_4) = 54$ and $R_u(\mathbf{w}) = 1 - \frac{3}{4} \times 2^{1/3}$.
(A.4)

(2) If $v_1 < v_2 + v_3 + v_4$, then $p_1 > 0$. Let $\delta > 0$ be small enough so that $p'_1 = p_1 - \delta(1 - p_1) > 0$. Let $p'_i = (1 + \delta)p_i$, $i = 2, 3, 4$. Then $p'_1 + p'_2 + p'_3 + p'_4 = 1$. It can be verified that for any $v'_1 > v_1$,

$$Q(v'_1, v_2, v_3, v_4) \leq \frac{v'_1 + v_2 + v_3 + v_4}{v'_1 p'_2 p'_3 p'_4 + v_2 p'_1 p'_3 p'_4 + v_3 p'_1 p'_2 p'_4 + v_4 p'_1 p'_2 p'_3} < Q(v_1, v_2, v_3, v_4)$$

for small enough $\delta > 0$. On the other hand, it can be verified that

$$\lim_{v_1 \uparrow (v_2 + v_3 + v_4)} Q(v_1, v_2, v_3, v_4) = Q(v_2 + v_3 + v_4, v_2, v_3, v_4) = 54$$

regardless of the values of v_2, v_3, v_4 . So by (A.4) the maximum of $R_u(\mathbf{w})$ is $1 - \frac{3}{4} \times 2^{1/3}$ under the restriction $v_1 < v_2 + v_3 + v_4$. $\square$
